(Dated: April 6, 2017)

We investigate the glass and the jamming transitions of hard spheres in finite dimensions d, through a revised cell theory, that combines the free volume and the Random First Order Theory (RFOT). Recent results show that in infinite dimension the ideal glass transition and jamming transitions are distinct, while based on our theory we argue that they indeed coincide for finite d. As a consequence, jamming results into a percolation transition described by RFOT, with a static length diverging with exponent $\nu = 2/d$, which we verify through finite size scaling, and standard critical exponents $\alpha = 0$, $\beta = 0$ and $\gamma = 2$ independent on d.

The transition between a fluid to an amorphous solid phase is common to many disordered systems, such as molecular liquids, colloids, granular materials and foams, and its understanding is one of the major problems in condensed matter. In a seminal paper [1], an universal jamming phase diagram was proposed to unify the transition of structural arrest of different systems, including the glass and the jamming transitions. However, within a mean field or the infinite dimensionality limit a distinction between the glass transition of liquids and the jamming transition of granular materials was posed in an analytical study of frictionless hard sphere particles [3–5]. As illustrated in Fig. 1a, this approach predicts that on increasing the pressure, the equilibrium liquid line reaches a dynamical transition point, and then terminates at an ideal glass transition critical point, just like in the Random First Order Transition (RFOT) scenario first introduced by Kirkpatrick, Thirumalai and Wolynes [6] and later developed by Wolynes and collaborators [7, 8]. At higher pressure, the mean field approach predicts a glass transition line that ends in the infinite-pressure limit at a jamming transition point. Here the gap between neighbour particles vanishes with a critical exponent, as the pressure diverges. Surprisingly this and other critical exponents are found [5] to be consistent with those found numerically in finite dimensions [9, 10].

One important question is whether this overall scenario survives in finite dimensions. Some effects of the finite dimensionality are already known. For instance, it is known that the mean field dynamical transition point [11, 12], smears out in finite dimension. The survival of the ideal glass transition associated with a static critical point is instead still a matter of debate. According to RFOT, the dynamical transition becomes a crossover towards the ideal glass transition, where a static critical length associated to the cooperative rearranging regions [6–8], as originally introduced by Adam and Gibbs [13], diverges. However, it is not clear whether the ideal glass transition and the jamming transition would coincide or not in finite dimension.

In this Letter, we investigate the relation between the glass and the jamming transitions in finite dimensions, extending the Cell Theory of the Glass Transition [14], which reproduces the essential features of Free Volume Theory [2, 15, 16]. The extended theory takes into account also the existence of cooperatively rearranging regions [6–8]. As a consequence, local properties like the free volume distribution are modified due to the presence of the cooperative length. Starting from this free volume distribution, we give arguments indicating that for hard sphere systems the cooperative length diverges at the jamming transition density. As a consequence, as illustrated in Fig. 1b, the ideal glass critical density ρ_K coincide with an *ideal* jamming density ρ_j, where the cooperative length diverges as $\xi \sim (\rho_j - \rho)^{-\nu}$, with $\nu = 2/d$ according to the RFOT. The identification of these two transitions is supported by the fact that ξ results proportional to the hyperuniform length, considering that hyperuniformity has been proposed as an essential property of the maximum jamming density [21–24]. We checked the prediction for ν via large-scale simulations using finite size scaling at the jamming transition, where we find numerical values in $2d$ and $3d$ in excellent agreement with the predicted exponent $\nu = 2/d$. This critical point can be described as a mixed order percolation transition, with the order parameter jumping discontinuously at the transition, $\beta = 0$, the mean cluster size diverging with exponent $\gamma = 2$, and the number of clusters of size ξ vanishing with an exponent $2 - \alpha = 2$ independent on the dimensionality. We name this percolative description of the RFOT theory Random First Order Percolation Transition, RFOPT. This scenario is quite different from other mixed-order percolation transition, such as the bootstrap percolation [17–20]. The hallmark of RFOPT is the presence of critical exponents that do not depend on the dimensionality, which is a typical property of the

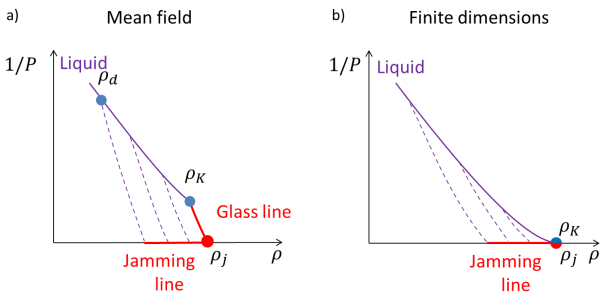

FIG. 1: Schematic phase diagram for a hard sphere system. The full line represents the equilibrium equation of state, while dashed lines represent out-of-equilibrium compression protocols. The infinite pressure limit of these lines define the jamming line. Panel a illustrates mean field results elaborated from Fig. 4 of Ref. [4], while panel b illustrates the finite dimensional scenario suggested in this paper. Here the ideal glass transition critical density ρ_K coincides with an ideal jamming critical density ρ_j, both being located at the end of an equilibrium line.

jamming transition.

Cell Theory – We start by shortly reviewing the Cell Theory of the Glass transition [14, 25, 26], that combines lattice theories of liquids [27] and the ideas of inherent structures, free-volume theory, and geometrical packing properties to understand the complex dynamics of glass-forming liquids, granular packings, and amorphous solids. In the lattice theory of liquids [27], the system is divided in N identical cells each corresponding to the unitary cell of the underlying crystal. Analogously, in the cell theory of glass–forming liquids, the system is divided in N Voronoï cells corresponding to the generic underlying inherent state, but one also considers that there are Ω different inherent states. Consequently, the partition function of a system of N hard sphere particles in a volume V is:

$$Z = \sum_{\{N(\mathbf{n})\}} \Omega(\{N(\mathbf{n})\}) e^{-\beta F(\{N(\mathbf{n})\})}, \qquad (1)$$

where

$$F(\{N(\mathbf{n})\}) = -kT \sum_{\mathbf{n}} N(\mathbf{n}) y\big[\ln \frac{v_f(\mathbf{n})}{\Lambda^d \mathcal{P}(\mathbf{n})}\big], \qquad (2)$$

is the free energy of the inherent states [14, 25, 26], Λ is the de Broglie length, $v_f(\mathbf{n})$ is the *'free volume'* associated with a particle in a cell, and $\mathbf{n}$ is a discrete index referring to the properties of the cell. $\mathcal{P}(\mathbf{n})$ is associated with the probability to find a cell with $\mathbf{n}$ that is single-occupied [27]. The quantity $\Omega(\{N(\mathbf{n})\})$ in Eq. 1 counts the number of distinct space–partitions (associated with the inherent states) made with the same set of $\{N(\mathbf{n})\}$. The key elements to be estimated in Eq. 2 are $\mathcal{P}(\mathbf{n})$ and $\Omega(\{N(\mathbf{n})\})$. At high density, which will be always considered throughout the paper, all Voronoï cells are essentially singly occupied and $\mathcal{P}(\mathbf{n}) \sim 1$. $\Omega(\{N(\mathbf{n})\})$ can be estimated [14, 25, 26] as the number of distinct configurations that can be made by positioning in different ways the N cells distributed in groups of $N(\mathbf{n})$, namely $\Omega(\{N(\mathbf{n})\}) = N!/\prod_{\mathbf{n}} N(\mathbf{n})!$. The partition function, Eq. 1, can be calculated via a saddle-point approximation, where the sum over all the distributions $\{N(\mathbf{n})\}$ is replaced with the contribution from a distribution $N^*(\mathbf{n})$ which minimizes the total free energy $\ln Z$. From this [14, 25, 26], it is possible to derive the distribution of the free volumes, that in the continuum limit becomes $p(v_f) = \frac{4}{\Gamma(2)} \frac{v_f}{\langle v_f \rangle^2} \exp\Big(-2\frac{v_f}{\langle v_f \rangle}\Big)$, where $\langle v_f \rangle$ is the average free volume per particle and $\Gamma(.)$ is the Gamma function. The distribution essentially coincides with the distribution originally evaluated within the free volume theory [2, 15, 16], which predicts a simple exponential form.

Extended Cell Theory – The cell theory can be extended to take into account the presence of the cooperatively rearranging regions of RFOT [6–8]. Within RFOT the system is partitioned in droplets of linear size ξ that, as in first-order transitions, have a free energy of nucleation containing a volume term plus a surface term. The surface term is proportional to ξ^θ with $\theta = d/2$, d being the space dimension (see also [28, 29] for further elaboration and a discussion of other possible values of θ). The theory predicts that the configurational entropy s_c vanishes as the size of the droplet diverges $s_c \sim 1/\xi^{d-\theta}$, while the relaxation time diverges exponentially. The presence of the droplets reduces the number of degree of freedom, N, by a factor $\lambda = (\xi/r_0)^{d-\theta}$, with r_0 a characteristic size such that $\rho r_0^d = 1$, with ρ being the particle density. Within the cell theory, this leads to a reduction in the number of configurations Ω, appearing in the partition function, Eq. 1, which now becomes $\Omega(\{N(\mathbf{n})\}) = \frac{(N/\lambda)!}{\prod_{\mathbf{n}}(N(\mathbf{n})/\lambda)!}$, and using Stirling's approximation:

$$\ln \Omega(\{N(\mathbf{n})\}) \simeq -\sum_{\mathbf{n}} \frac{N(\mathbf{n})}{\lambda} \ln \frac{N(\mathbf{n})}{N}. \qquad (3)$$

Following the same procedure as for the case $\lambda = 1$ we derive a new free volume distribution

$$p(v_f) = \frac{k^k}{\Gamma(k)} \frac{v_f^{k-1}}{\langle v_f \rangle^k} \exp\Big(-k\frac{v_f}{\langle v_f \rangle}\Big), \qquad (4)$$

with [30] $k = 1 + \lambda$. From Eq. 1, Eq. 3 and Eq. 4 we find:

$$\frac{\ln Z}{N} = \int p(v_f) \ln \frac{v_f}{\Lambda^d} dv_f + s_c, \qquad (5)$$

where $s_c = -\frac{B}{\lambda}$ is the configurational entropy, Eq. 3, with $B = \int p(v_f) \ln p(v_f) dv_f$ being a smooth function of $\langle v_f \rangle$. Since $\lambda = (\xi/r_0)^{d-\theta}$, we recover $\xi \propto s_c^{\frac{1}{\theta-d}}$ as in RFOT. Using the Kauzmann assumption, $s_c \propto (\rho_K - \rho)$, and

$\theta = d/2$, the critical behaviour of the correlation length is $\xi \propto (\rho_K - \rho)^{-2/d}$.

We now argue that the cooperative length ξ does actually diverge at the jamming transition density ρ_j, where $\langle v_f \rangle = 0$. This implies $\rho_j = \rho_K$. Note first that the free volume distribution Eq. 4 tends to a delta function in the limit $k + (\xi/r_0)^{d-\theta} \to \infty$. So if ξ diverges at a value $\langle v_f \rangle = v_K > 0$, as well as for $\langle v_f \rangle < v_K$, then $p(v_f) \propto \delta(v_f - \langle v_f \rangle)$ for $v_K \geq \langle v_f \rangle \geq 0$, corresponding to the density interval ranging from the ideal glass transition, $\rho = \rho_K$, to the ideal jamming transition, $\rho = \rho_j$. This is contrary to the expectation that only at jamming the distribution would be a delta function. Consequently ξ must diverge at the jamming point, and $\rho_j = \rho_K$, and

$$\xi/r_0 \sim (\rho_j - \rho)^{-2/d}. \tag{6}$$

Note that, sice $p(v_f)$ approaches a delta function for $\langle v_f \rangle \to 0$, our approach predicts that the ideal jammed configuration has no rattlers.

From this relation one determines the dependence of k on ρ and therefore, assuming [31] $\langle v_f \rangle^{1/x} = A(\rho_j - \rho)$ where A is a constant, the dependence of k on $\langle v_f \rangle$. This allows to derive the equation of state from Eq. 4 and Eq. 5, $P = k_B T \Big(\partial \ln Z / \partial V \Big)_{N,T}$,

$$\frac{P}{N k_b T} = \frac{x}{V - V_J}. \tag{7}$$

Here $\rho_j = N/V_j$ is the jamming density corresponding to infinite pressure. Free volume theory [32] predicted Eq. 7 with $x = d$, which has been numerically verified for hard sphere systems [31, 33].

From Eq. 7 we find the compressibility to vanish at the jamming transition as $\kappa_T \sim (\rho_j - \rho)^2$. Using Eq. 6 it follows that the relation between the compressibility and the cooperative length is given by $\kappa_T \sim (\xi/r_0)^{-d}$. Interestingly the vanishing of the compressibility in monodisperse jammed particles has been linked to the concept of hyperuniformity. More precisely close to the jamming glass state in $3d$ it was found $\kappa_T \sim (\xi_{DCF})^{-3}$, where ξ_{DCF}, is a diverging length defined through to the direct pair correlation function [21–23]. This imply that in 3d the hyperuniform length and the cooperative length are related and that at the jamming glass transition $\xi \sim \xi_{DCF}$. Moreover, Atkinson et al [24] have suggested that exact hyperuniformity implies the maximally random jammed packings, characterized by absence of rattlers, all properties predicted by our theory at the glass jamming transition.

Random First Order Percolation Transition – The above results allow to interpret the jamming glass transition as a percolation transition, we name Random First Order Percolation Transition. This is a percolation transition of compact clusters of linear dimension ξ and fractal dimension $D = d$ [34–36], one could identify through a set-to-point correlation approach [37]. The size s^* of the critical cluster is given by $s^* \sim \xi^d$. As the transition is approached the density of critical clusters vanishes as ξ^{-d}, and the percolation probability jumps discontinuously from 0 to 1. Adapting the standard scaling ansatz [39–41] for the cluster size distribution $n(s)$ to this peculiar random first-order percolation, we obtain $n(s) \sim 1/s^\tau f(s/s^*)$, where $f(x)$ is a rapidly decreasing function for $x \gg 1$, that scales as $f(x) \propto x^{-\tau}$ with $\tau = d/D + 1 = 2$ for $x \ll 1$. The density of clusters scales as $\int n(s) ds \propto \xi^{-D(\tau-1)} \propto (\rho_j - \rho)^{2-\alpha}$, and thus $\alpha = 0$ given Eq. 6. The mean cluster size $S = \sum s^2 n(s)$ diverges at jamming as a power law $S \sim (\rho_j - \rho)^{-\gamma}$ with $\gamma = \nu(d + D)/2 = 2$. The critical exponent associated to the order parameter is $\beta = \nu(d - D) = 0$. Summarizing, these exponents satisfy the scaling and hyperscaling law:

$$2\beta + \gamma = 2 - \alpha = d\nu. \tag{8}$$

Interestingly we have $\alpha = 0$, $\beta = 0$, $\gamma = 2$ which are independent on the dimensionality. A similar independence of the critical exponents on the dimensionality characterizes the jamming transition. The only exponent depending on the dimensionality is ν that equals $2/d$. This exponent can be estimated via standard finite-size scaling of the jamming transition density, $\Delta\rho(N) = \rho_j^* - \rho_j(N)$, where ρ_j^* is the estimated jamming density in the thermodynamic limit, and of the width of the jamming probability distribution, $\sigma(N)$, that scale as $\Delta\rho \propto \sigma \propto N^{-1/d\nu}$. Literature investigations [10, 42] of these scaling relations do not unambiguously fix the value of ν [43]. We have evaluated the probability distribution of the jamming thresholds through large-scale simulations. Our results, reported in Fig. 2, show that $\Delta\rho \propto \sigma \propto N^{-1/2}$ in both $2d$ and $3d$, consistently with our theoretical prediction, $\nu = 2/d$.

We stress that this scenario refers to the transition as approached from the unjammed phase, the other side of the transition being not accessible in hard-sphere systems. In soft sphere systems, one might observe different geometrical exponents above the transition should the jammed and the unjammed phase be separated by a singularity [44]. In addition, above the transition other exponents, satisfying their own scaling relations, describe the elastic response of the system [45].

Conclusions – In conclusion using a cell theory previously developed, combined with the Adam-Gibbs-Wolynes cooperative rearranging region approach, we have suggested that for a hard sphere system in finite dimension the ideal glass transition, where the cooperative length of the RFOT diverges, coincides with the ideal jamming transition which occurs at infinite pressure at the end of an equilibrium line where the jamming density is maximal without rattlers, as in Fig. 1b. Following [7, 13], the relaxation times τ diverges a la Vogel-Fulcher on approaching the jamming glass critical density, $\frac{\tau}{\tau_0} = \exp\left(A/(\rho_j - \rho)\right)$. Using the properties of

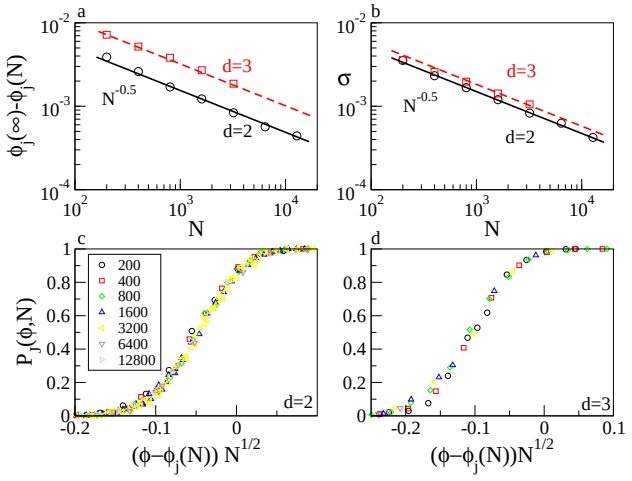

FIG. 2: Jamming probabilities of a 50:50 mixture of spherical N particles interacting via a Harmonic potential, with size ratio 1.4. The system is prepared in a random configuration, and its energy is then minimized via the conjugate gradient protocol [10, 42]. The jamming probability is computed as the average over 500 independent minimizations for every system size N and volume fraction $\phi = \rho v_p$, with v_p average particle volume. The distributions are well approximated by an error function, from which we extract a typical size dependent jamming volume fraction, $\phi_J(N)$, and a width, $\sigma(N)$. We find $\phi_J(\infty) - \phi_J \propto N^{-1/2}$, as illustrated in panel a, and $\sigma(N) \propto N^{-1/2}$, as illustrated in panel b, in both $d = 2$ and $d = 3$. Panel c and d illustrate the scaling of the jamming probabilities, respectively in $d = 2$ and in $d = 3$, for the different values of N reported in the legend.

the RFOT theory we have been able to describe this glass jamming critical point as a Random First Order Percolation Transition. This allows rationalizing the critical behaviour of the jamming transition in terms of an order parameter which jumps discontinuously, a critical length with a critical exponent dependent on the dimensionality, and all other critical exponents independent on the dimensionality. These exponents satisfy scaling laws typical of critical phenomena, Eq. 8. We note that it is possible to associate other critical exponents to the jamming transition. This is common within percolation theory where, besides usual critical exponents obeying standard scaling laws, many other critical exponents are introduced, related to quantities, like shortest path, backbone, elastic properties and so on [39–41], reflecting structural properties of the critical clusters. In summary, our work provides insights that change the current theoretical interpretation of the relation between the glass and the jamming transitions, supporting the original suggestion of Ref. [1], and proposing a novel percolative interpretation of this transition inspired by RFOT.
